One of the more interesting hypotheses about the behavior of natural selection on genes comes from a study I started when I was a graduate student (if you're interested in this sort of thing, I've written an entry about it for PhilPapers). The basic idea is simple: a gene that has more copies has

an advantage. But as a gene copies itself, and the copies of the gene are passed on to the next generation, it changes, and its effects on fitness change. So if a gene has lots of copies in one generation, the gene may have a new effect on fitness in a subsequent generation. We'll call this the "genetic load" of the gene, and it's something that is created in the process of gene duplication. The effect on fitness is therefore a product of two things: how many copies of the gene there are, and how well the gene works. That is, the fitness effect is determined by a combination of the "load" of the gene and the "strength" of the gene. Of course, this is only a hypothesis. As I argued in the paper, the concept is still in its infancy. But it's a hypothesis that has some conceptual elegance. I wrote my thesis about this concept and has kept it in my head since I graduated. When I found the paper by Purugganan and Bais, I found myself thinking, "Oh my gosh, I'm right!" I thought that the concept had been around for a long time, but I couldn't find the name for it. Today I got to work on the letter, and it turns out the hypothesis was only popularized by the purposeful efforts of Timothy F. C. Purugganan. The paper that first came to my attention was from 1976, "Shifts in the Effect of Genes: A Model for Evolution" published in Genetics. However, that paper didn't really explain the idea in much detail, and
